A novel method to one-pot-synthesize high-quality In$_2$O$_3$@In$_2$S$_3$ core–shell nanoparticles, consisting of a step of reducing In$_2$O$_3$ core surface into a layer of active indium metal in high-temperature organic solution and a step of converting this layer to In$_2$S$_3$ using CS$_2$, has been developed.

Although study of semiconductor core–shell nanoparticles (NPs) has attracted increasing scientific and technological interest due to the ability to fine-tune their properties, the most extensive syntheses were focused on type-I core–shell NPs,$^5$–$^8$ in which a wide bandgap material is coated onto the core of a narrow bandgap material. There have been relatively rare reports concerning the preparation of reverse type-I core–shell NPs,$^9$ in which a narrow bandgap material is overgrown on the core of a wide bandgap material and unique characteristic may be observed. Indium oxide (In$_2$O$_3$), widely used in solar cells and optoelectronic devices,$^{10}$ is a direct wide bandgap and photostable$^{11}$ material ($\sim$3.6 eV),$^{12}$ whereas indium sulfide (In$_2$S$_3$) is a visible-light-sensitive semiconductor with a bandgap as narrow as $\sim$2.00–$\sim$2.30 eV (bulk)$^{13}$–$^{15}$ (see Scheme 1). It has already demonstrated that the In$_2$O$_3@$In$_2$S$_3$ core–shell structure as electrodes on micrometer-level could generate high anodic photocurrent.$^{11,16}$ Here we demonstrate a feasible and simple approach to one-pot-synthesize high-quality In$_2$O$_3@$In$_2$S$_3$ core–shell particles on the nanometer level.

The preparation of In$_2$O$_3@$In$_2$S$_3$ core–shell NPs involves an initial synthesis of In$_2$O$_3$ nanocrystals (NCs), a subsequent reduction of the surface of In$_2$O$_3$ NCs, and a further sulfidization to form In$_2$S$_3$ shells. It has been reported that nano-scale In$_2$O$_3$ can be prepared through various reaction routes, such as oxidation by trimethylamine oxide (TMNO),$^{10}$ aminolysis of the InP surface by oleylamine,$^8$ and alcoholysis in organic solvent.$^1$ In consideration of the next reduction procedure, we modified our previous strategy of In$_2$O$_3$ synthesis$^{10}$ by altering the heating rate and skipping the oxidizing step in which TMNO was involved. Generally, TMNO could assist in refining the morphology of In$_2$O$_3$ NCs, such as octahedral shape, which is obviously not a significant consideration in the current approach.

In a typical experiment, 0.20 mmol of indium acetate (99.99%), 0.60 mL of oleic acid (90%) and 0.80 mL of oleylamine (70%, all chemicals were from Aldrich without further purification) were combined with 5.0 mL of octadecene in a three-necked round-bottomed flask equipped with a condenser in a fume hood. Standard air-free techniques were used. The vigorously stirred mixture was heated to 120 °C under an argon purge. This temperature was held for 20 min and then rapidly raised to 320 °C at a rate of 15 °C min$^{-1}$ and the system was vigorously agitated and refuxed for an additional 40 min under an argon stream. During this reflux period, the transparent yellow mixture became a slurry at $\sim$300 °C, subsequently changed to clear yellow again in $\sim$1 min, and finally turned light brown. When the mixture was cooled to 140 °C, 1 mL of the colloidal In$_2$O$_3$ suspension was collected using a glass syringe with a long needle into 30 mL of anhydrous ethanol$^{18}$ followed by centrifugation and re-dispersion into a certain amount of anhydrous hexane as a “core” sample for the purpose of comparison. It has recently been reported that WO$_3$ nanorods could be converted into WS$_2$ nanosheets using CS$_2$ at high temperature.$^{19}$ To achieve core–shell NPs in our system, we performed a reduction and a subsequent sulfidization in the same flask. Typically, 0.5 mL of freshly prepared superhydride solution in dioctyl ether$^{20}$ (1.0 M) was injected into the rest of the reaction system at 140 °C under argon protection. After agitation for 30 min, 0.5 mL of CS$_2$ solution in toluene (0.4 M) was further injected into the flask and the color of the solution immediately turned orange. The system was continuously stirred for 20 min, followed by an additional 35 min vigorous agitation when the temperature was increased to 250 °C at a rate of 5.5 °C min$^{-1}$. In order to trap the excess CS$_2$ which is highly toxic, the exhaust stream from the reaction system was introduced into a bottle containing excess ethanol before it was released into the fume hood. The resultant colloids were

![Scheme 1 Bandgap energy levels in In$_2$O$_3$ and In$_2$S$_3$.](image-url)
cooled to room temperature and isolated by adding anhydrous ethanol, and collected by centrifugation. The resulting white-grey precipitate could be partially re-dispersed in anhydrous hexane, forming a suspension of In$_2$O$_3$@In$_2$S$_3$ core–shell NPs with a very narrow distribution of particle size. The capability of dispersion in hexane could be enhanced by adding a drop of oleic acid.

The morphology and phase structure of these core–shell NPs were evaluated using transmission electron microscopes (TEM) (Hitachi 7600 & 9500, HD 2000) and an X-ray diffractometer (XRD) (PANalytical X-pert system), respectively. A typical TEM image of In$_2$O$_3$ NCs in low magnification is shown in Fig. 1A, showing that the In$_2$O$_3$ NCs possess an average diameter of ~10 nm and a short-range, hexagonal order of self-assembled pattern. Fig. 1B shows the structure of In$_2$O$_3$@In$_2$S$_3$ core–shell NPs in low magnification, revealing that the average diameter of the entire core–shell NPs is ~16 nm, which is broken down into a ~8 nm diameter of the In$_2$O$_3$ cores and a ~4 nm thickness of the In$_2$S$_3$ shells (also see Fig. S1 in ESI†). This observation also demonstrates “shrinkage” of the In$_2$O$_3$ NCs from ~10 to ~8 nm in diameter due to the surface reduction by superhydride, indicating that the In$_2$O$_3$ surface of ~1 nm thickness was reduced to highly active In and subsequently converted to a In$_2$S$_3$ layer of thickness ~4 nm. In this shell-formation process, highly active elemental sulfur was freshly provided by the thermal decomposition of CS$_2$. As displayed in Fig. 1C, the core–shell structure can be verified by the high resolution TEM (HRTEM) image, demonstrating well-developed lattice structures on both core and shell portions (also see Fig. S1c in ESI†). The lattice pattern of In$_2$O$_3$ core is well-resolved and shows a single crystalline structure; whereas the highly crystalline shell can be further identified as In$_2$S$_3$ based on the measured lattice distance of 3.22 Å which is considerably consistent with that (d = 3.25 Å) of tetragonal In$_2$S$_3$ lattice planes [109].

In$_2$S$_3$ shell is the changes of the relative intensities at those peaks. For the core–shell NPs, the peak at 422 nm almost vanishes and the relative intensity of the peak at 440 nm apparently decreases, whereas all of other peaks can be determined with relatively enhanced intensities. It is well known that bulk In$_2$O$_3$ has no PL emission at room temperature. However, many researchers reported the emission of In$_2$O$_3$ NCs, nanowires, and nanocubes, and they were mainly attributed to deeper energy level emissions and oxygen deficiency emissions although the PL emission mechanism of In$_2$O$_3$ is still ambiguous. In our case, the PL emissions are in the near UV and visible region when excited at the far UV region. The In$_2$S$_3$ shell does not change the positions of In$_2$O$_3$ emission but it does alter the relative intensities. Due to the fact that there may be oxygen deficiencies at the interface of the core–shell and the core of wide bandgap In$_2$O$_3$ surrounded by the narrow bandgap In$_2$S$_3$, the energy could be transferred from the conduction band of In$_2$O$_3$ to the upper energy level of the In$_2$S$_3$ shell and to the energy level of oxygen deficiency when a sample is excited by a light with wavelength in the far UV region, resulting in a decrease of the near band-edge emission (422 nm and 440 nm) and an increase of oxygen deficiency emission. We therefore attribute the emission at 422 nm and 440 nm to the near band-edge emission and the other peaks should be related to the oxygen deficiency. In order to correlate the PL changes (which are associated with the In$_2$S$_3$ shell formation) with various reaction parameters, we examined the PL spectra under different reaction conditions. Several typical PL spectra recorded with different reaction parameters including the amount of reducing agent (super-hydride), the reducing time, excess CS$_2$ and the sulfidization time, are given in Fig. S2 in ESI.† It seems that the reduction process is a key step compared with the sulfidization for the formation of In$_2$S$_3$ shells.

In conclusion, we have successfully synthesized In$_2$O$_3$@In$_2$S$_3$ reverse type-I core–shell NPs using our recently developed one-pot reduction method in solution. The existence of the In$_2$S$_3$ shell is confirmed by HRTEM, EDS and XRD investigations. The TEM images also clearly reveal the partial reduction of the In$_2$O$_3$ core on the surface (core diameter “shrinks”) and the formation of the highly crystalline In$_2$S$_3$ shell. The optical studies suggest that the PL emissions at 422 and 440 nm could be attributed to the near band-edge emission and the other emissions at 461, 484 and 533 nm should be related to the oxygen deficiency. This approach may be able to extend to the syntheses of other sulfide core–shell NPs.
